Enos

INTRODUCTION: Carbonaceous asteroids formed early in Solar System history and experienced varying degrees of aqueous (water-rock) and thermal alteration. Most models of the evolution of these asteroids suggest that aqueous alteration was driven by hydrothermal convection. However, it is debated whether this alteration occurred in a chemically closed or open system. The bulk chemical compositions of the carbonaceous chondrite meteorites imply that the system was closed. Models predict that large-scale fluid flow in an open system took place on at least some asteroids. In this scenario, fluids would have flowed through fractures from the interior, and minerals would have precipitated into these fractures, forming veins.

RATIONALE: Global spectral observations by the OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security-

Regolith Explorer) spacecraft have shown that carbon-bearing materials, including organics and/or carbonates, are widespread on the surface of near-Earth asteroid (101955) Bennu. To understand the composition of these carbon-bearing materials and their implications for Bennu's aqueous alteration history, we examined visible–near-infrared spectra obtained at resolutions of ~4 m in the region around the mission's primary sampling site, Nightingale. We compared these spectra with laboratory spectra of organics and carbonates. Broad-band panchromatic images of the Nightingale region at pixel scales of ~1.4 cm allowed us to search for surface features that could contextualize the spectral data.

RESULTS: On the basis of the wavelength position and shape of spectral absorption features, the closest matches to a subset (~15%) of

spectra collected in the Nightingale region are the carbonate minerals calcite, dolomite, and magnesite, with calcite being the most prevalent. These minerals are found in the highly aqueously altered CM- and CI-group carbonaceous chondrites, proposed meteorite analogs of Bennu.

Bright, centimeters-thick, roughly meter-long veins are apparent in images of some boulders near the Nightingale site. The veins have albedos of 10% to at least 19%, much brighter than Bennu's average of 4.4%. These albedos are consistent with the veins being filled by carbonates with minor abundances of opaque materials such as magnetite and organics. The albedos are too high for the veins to be dominantly composed of organics or any other material that has been identified on Bennu, except carbonates.

There are only a few bright vein-filling materials found in meteorites, and carbonate is the only one of these that is plausibly present on Bennu. Linear mixture modeling suggests that only a small fraction of a spectrometer field of view (<1%) needs to contain carbonate to explain the observed spectral signatures, which is consistent with the observed extent of the veins.

CONCLUSION: The observed bright veins on Bennu are most likely dominantly composed of carbonates. The detection of these meter-sized, putative carbonate veins indicates that extensive water flow occurred in a chemically open hydrothermal system on the larger parent asteroid of Bennu, before the catastrophic disruption of the parent asteroid led to Bennu's reaccumulation as a rubble pile. Kinetic modeling assuming a calcite vein composition shows that a hydrothermal system kilometers in size, with alteration likely taking place over thousands to millions of years, would have been needed to create veins of the dimensions preserved in the constituent boulders of Bennu.

Some CM- and CI-group meteorites have very small (micrometers to millimeters) carbonate veins or presumed vein fragments; veins on the scale that we observe on Bennu are not present in meteorites. It is possible that such veins are present on other carbonaceous asteroids that have not been observed by spacecraft. We predict that the sample of Bennu's surface material that is planned to be returned to Earth by the OSIRIS-REx spacecraft will contain carbonates and that they will be distributed with a structure and scale distinct from those that occur in meteorites. ■

OSIRIS-REx panchromatic image (~1.4 cm pixel⁻¹) showing a boulder with a bright vein on Bennu.

This linear feature is more than twice as bright as the surrounding rock. Its most plausible composition is carbonate, suggesting that a large, long-lived hydrothermal system operated on Bennu's parent asteroid. The image was collected by the PolyCam imager on 26 October 2019 at 61.60°N, 50.57°E.

The composition of asteroids and their connection to meteorites provide insight into geologic processes that occurred in the early Solar System. We present spectra of the Nightingale crater region on near-Earth asteroid Bennu with a distinct infrared absorption around 3.4 micrometers. Corresponding images of boulders show centimeters-thick, roughly meter-long bright veins. We interpret the veins as being composed of carbonates, similar to those found in aqueously altered carbonaceous chondrite meteorites. If the veins on Bennu are carbonates, fluid flow and hydrothermal deposition on Bennu's parent body would have occurred on kilometer scales for thousands to millions of years. This suggests large-scale, open-system hydrothermal alteration of carbonaceous asteroids in the early Solar System.

The Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer (OSIRIS-REx) mission to asteroid (101955) Bennu is designed to return a carbon-rich sample of the asteroid to Earth (1). Bennu, a 500-m-diameter near-Earth asteroid, was chosen as the mission target because of its spectral similarity to primitive and organic-rich carbonaceous chondrite meteorites (2). Primitive chondritic meteorites formed in the early Solar System, so they may record the materials, processes, and events that occurred during that period.

The OSIRIS-REx spacecraft entered orbit around Bennu in December 2018. Throughout 2019 and early 2020, the spacecraft acquired images and spectra to characterize Bennu's surface properties, composition, and relationship to meteorites, in advance of sample collection.

Bennu is spectrally classified as a B-type asteroid on the basis of its blue (negative) spectral slope. B-types are a subset of the

larger C-complex of primitive asteroids, so-named for their presumably carbonaceous compositions. Bennu's surface contains abundant, widespread hydrated minerals (3), has widespread magnetite (3, 4), and is dominated by boulders up to ~100 m in longest dimension (5). Near-infrared spectra of Bennu's surface exhibit an absorption feature due to hydroxyl in hydrated clay minerals; the band minimum is 2.74 μm , most consistent with hydrated Mg-bearing phyllosilicates (3, 6). Thermal infrared spectra exhibit silicate stretching and bending modes consistent with volumetrically dominant phyllosilicates, as well as absorptions attributable to magnetite near 18 and 29.4 μm (555 and 340 cm^{-1}) (3). These observations demonstrate that Bennu is mineralogically similar to the carbonaceous chondrite meteorites that show evidence of water-rock interaction (i.e., aqueous alteration), with the closest meteorite analogs being the most heavily altered members of the CM and CI groups. Aqueous alteration of these meteorites likely took place on a large parent asteroid, >30 km in diameter (7), early in Solar System history (8). Dynamical analyses suggest that Bennu, a rubble pile asteroid, consists of fragments of a parent body of ~100-km diameter that reaccumulated after a catastrophic disruption (9–11).

Establishing Bennu's relationship with specific groups of meteorites—whether CI, CM, or others—would provide insight into the geologic processes that Bennu's parent body experienced. The CI and CM groups record diverse scenarios of parent body aqueous alteration. All known CI chondrites are categorized on the basis of their mineral and rock properties as petrologic type 1 (CI1) (12). This classifies the

CI1s as heavily hydrated, and they contain the highest abundances of volatile elements of any meteorites (13). CM chondrites span a broader range of degrees of aqueous alteration, from petrologic type 1 to 2 (14, 15). The CM chondrites are depleted in volatiles relative to the CI1s. Although the CM1 and CI1 meteorites are both highly aqueously altered, they have distinct bulk chemistry and textures (15). There are other carbonaceous chondrites that cannot be classified into any of the known groups and are therefore termed “ungrouped” (16). Grouping chondrites together implies that they likely originate from the same geologic context; if a carbonaceous chondrite is ungrouped, it is possible that it has a distinct geologic origin. We consider recent observations of asteroid Bennu within this meteorite framework, to constrain its geologic history and make predictions for the sample that will be returned to Earth.

Spectra of carbon species on Bennu

In global observations of Bennu collected during the Detailed Survey–Equatorial Stations campaign of the OSIRIS-REx mission (25 April to 6 June 2019) (1), the OSIRIS-REx Visible and InfraRed Spectrometer (OVIRS) (17) detected a ubiquitous infrared absorption feature near 3.4 μm (18), a spectral region associated with carbon-bearing species. OVIRS measures reflected light at wavelengths from 0.4 to 4.3 μm with a circular, 4-mrad field of view (17). Between 3.2 and 3.6 μm , there are at least five absorption minima attributed to organic molecules, including symmetric and asymmetric stretching modes of methyl ($-\text{CH}_3$) and methylene ($-\text{CH}_2$) groups (i.e., aliphatic CH), and an aromatic CH stretch. Carbonates have overlapping absorption features in this wavelength region from overtones (absorptions occurring at higher-energy multiples of the fundamental frequency) and combinations of the fundamental stretches in CO_3 .

The global data have a spatial resolution of ~30 m in the direction of spacecraft motion (along-track) and 20 m in the perpendicular direction (cross-track), with coverage of nearly the entire asteroid surface (18). The complex spectral features near 3.4 μm in this dataset are attributed at the global scale to mixtures of organics and carbonates (18). The spectral shape in this wavelength region is repeatable to <1% across multiple observations of the same surface spot, indicating that instrumental and illumination effects do not cause the observed absorption complexity (18).

We analyzed higher-spatial-resolution OVIRS observations that were collected in October 2019 during the first Reconnaissance (Recon A) phase of the OSIRIS-REx mission, which entailed more detailed investigations of candidate sampling sites. We used data from the region around Nightingale crater, the mission's

Fig. 1. Spectral features in OVIRS data compared to laboratory carbonate spectra. (A to C) Black points show the original OVIRS spectrum of Benu from three different locations in Nightingale, and the thick black lines are the spectrum smoothed with a 3σ Gaussian. The carbonate laboratory spectra (colored lines as indicated in the legends) are natural, terrestrial samples with variable cation content (table S1). All spectra have had their continuum removed and are offset.

primary sampling site, to provide context for the sample return. These observations have spatial resolutions of ~ 4 m cross-track and 9 m along-track for each OVIRS footprint.

The shapes of the $3.4\text{-}\mu\text{m}$ feature in the Nightingale observations differ from those in the global observations (18), indicating that it may be possible to distinguish compositions at higher spatial resolution. To discriminate between organics and carbonates, we use a chi-square goodness of fit test, band minima positions, and visual inspection (19). The goodness of fit test uses a set of 220 laboratory spectra of carbonates and organics with a range of compositions to assess how closely these laboratory data match the shape of the OVIRS data (table S1). Uncertainties were determined by adding noise to the laboratory spectra to mimic the OVIRS signal-to-noise ratio (SNR) near $3.4\text{ }\mu\text{m}$ (19). We find that chi-square values of <1 can identify either carbonate minerals or organics with $>99\%$ confidence ($>95\%$ confidence for chi-square < 2) (table S1).

Organic and carbonate spectral features differ in terms of number of minima, minima positions, and absorption widths. We identify some OVIRS spectra with $3.4\text{-}\mu\text{m}$ features that are consistent with carbonates and others that are consistent with organics (Figs. 1 and 2). The OVIRS spectral shapes consistent with organics are similar to those previously detected near $3.4\text{ }\mu\text{m}$ in asteroids [e.g., (20–22)] and me-

terites (23) (Fig. 2). These features have a narrow minimum at $3.42\text{ }\mu\text{m}$ or a broad, flat feature centered at $3.42\text{ }\mu\text{m}$ [e.g., (24)]. The OVIRS spectral signature consistent with carbonates is primarily identified by an absorption feature with two minima near $3.4\text{ }\mu\text{m}$ (Fig. 1). The band positions vary by tens of nanometers, consistent with known changes in wavelength of carbonate absorptions with varying cation composition (Fig. 3). The OVIRS spectra that are best fitted with carbonate laboratory spectra (Fig. 2) are poorly fitted with organic laboratory spectra (fig. S1).

The carbonate-matching OVIRS spectra include features similar to those of calcite (CaCO_3), siderite (FeCO_3), magnesite (MgCO_3), dolomite [$\text{CaMg}(\text{CO}_3)_2$], and/or breunnerite [$(\text{Mg,Fe,Mn})\text{CO}_3$] (Figs. 1 and 2). We cannot distinguish calcite and siderite at the spectral resolution and SNR of the OVIRS data near $3.4\text{ }\mu\text{m}$; however, Fe in siderite would produce a broad absorption near $1\text{ }\mu\text{m}$, which is not detected (fig. S2). Siderite is rare in carbonaceous chondrite meteorites, whereas calcite is abundant (24). We therefore conclude that calcite is the most likely carrier responsible for these carbonate-matching spectra. Aragonite has the same composition as calcite (CaCO_3) with a different crystal structure; its spectral properties are similar to those of calcite at wavelengths $<2.5\text{ }\mu\text{m}$ (25), but appropriate laboratory spectra are not available, so it is

not included in our analysis. Spectra that we identify as dolomite could alternatively be due to Fe-rich breunnerite, which has an absorption feature at a similar wavelength. For more Mg-rich forms of breunnerite, we expect the band position to shift toward shorter wavelengths, similar to magnesite. We have not found a $3.4\text{-}\mu\text{m}$ feature on Benu that corresponds to natrite (Na_2CO_3), which was detected in the brightest regions of dwarf planet Ceres and has minima at longer wavelengths than calcite (26).

In addition to the feature at $3.4\text{ }\mu\text{m}$, carbonates are expected to produce an absorption near $4\text{ }\mu\text{m}$. OVIRS has an SNR of 50 at $3.4\text{ }\mu\text{m}$, but the signal decreases rapidly beyond $\sim 3.6\text{ }\mu\text{m}$, with an SNR of only 15 at $4\text{ }\mu\text{m}$. Low SNR reduces our ability to detect the expected carbonate absorption near $4\text{ }\mu\text{m}$, but we do find a possible absorption feature in this region that is correlated with the $3.4\text{-}\mu\text{m}$ feature (fig. S2). Overtones at ~ 2.35 and, possibly, $2.55\text{ }\mu\text{m}$ are also observed in the OVIRS spectrum (fig. S2) and may be due to carbonate and/or Mg or Fe phyllosilicates. However, these features have $<2\%$ band depth, the strength of the absorption feature compared to the continuum, and any variation in band depth is within the uncertainty.

Thermal infrared spectra from the OSIRIS-REx Thermal Emission Spectrometer (OTES) (27) exhibit a spectral feature near $7.04\text{ }\mu\text{m}$ (1420 cm^{-1}) that may be attributable to carbonates (28), but this feature has not been definitively assigned (3). Another carbonate feature, the ν_3 (third fundamental) absorption, is expected at ~ 6.35 to $6.75\text{ }\mu\text{m}$ (1500 cm^{-1}) and has been observed in laboratory and remote-sensing data (28, 29); however, it has not been identified in OTES global spectral observations (spatial resolutions of 20 to 40 m). Nor have other expected carbonate features, including the narrow, ν_2 fundamental absorption near $11.3\text{ }\mu\text{m}$ (886 cm^{-1}) and a large, broad, fundamental absorption between ~ 25 and $33\text{ }\mu\text{m}$ (~ 400 to 300 cm^{-1}). Detection of spectral features in the thermal infrared depends on SNR, temperature, physical conditions (e.g., roughness or cavities), phase abundance, the compositions of the other phases that are present, spectral resolution, and particle size (19). These factors may explain the nondetection of these carbonate bands, despite the higher SNR of the OTES data relative to that of the OVIRS data.

We mapped a $\sim 0.03\text{-km}^2$ area surrounding the Nightingale sample site ($\sim 56.04^\circ$ latitude, 42.05° longitude), within which $\sim 1\%$ of the 3396 OVIRS spectra have a chi-square < 1 match to laboratory spectra of carbonates, rather than organics or mixtures, and $\sim 15\%$ have chi-square < 2 (Fig. 2) (19). Organics account for $<1\%$ (chi-square < 1) or 8% (chi-square < 2) of the spectra based on these goodness of fit tests. The spectral signatures with chi-square < 1 match

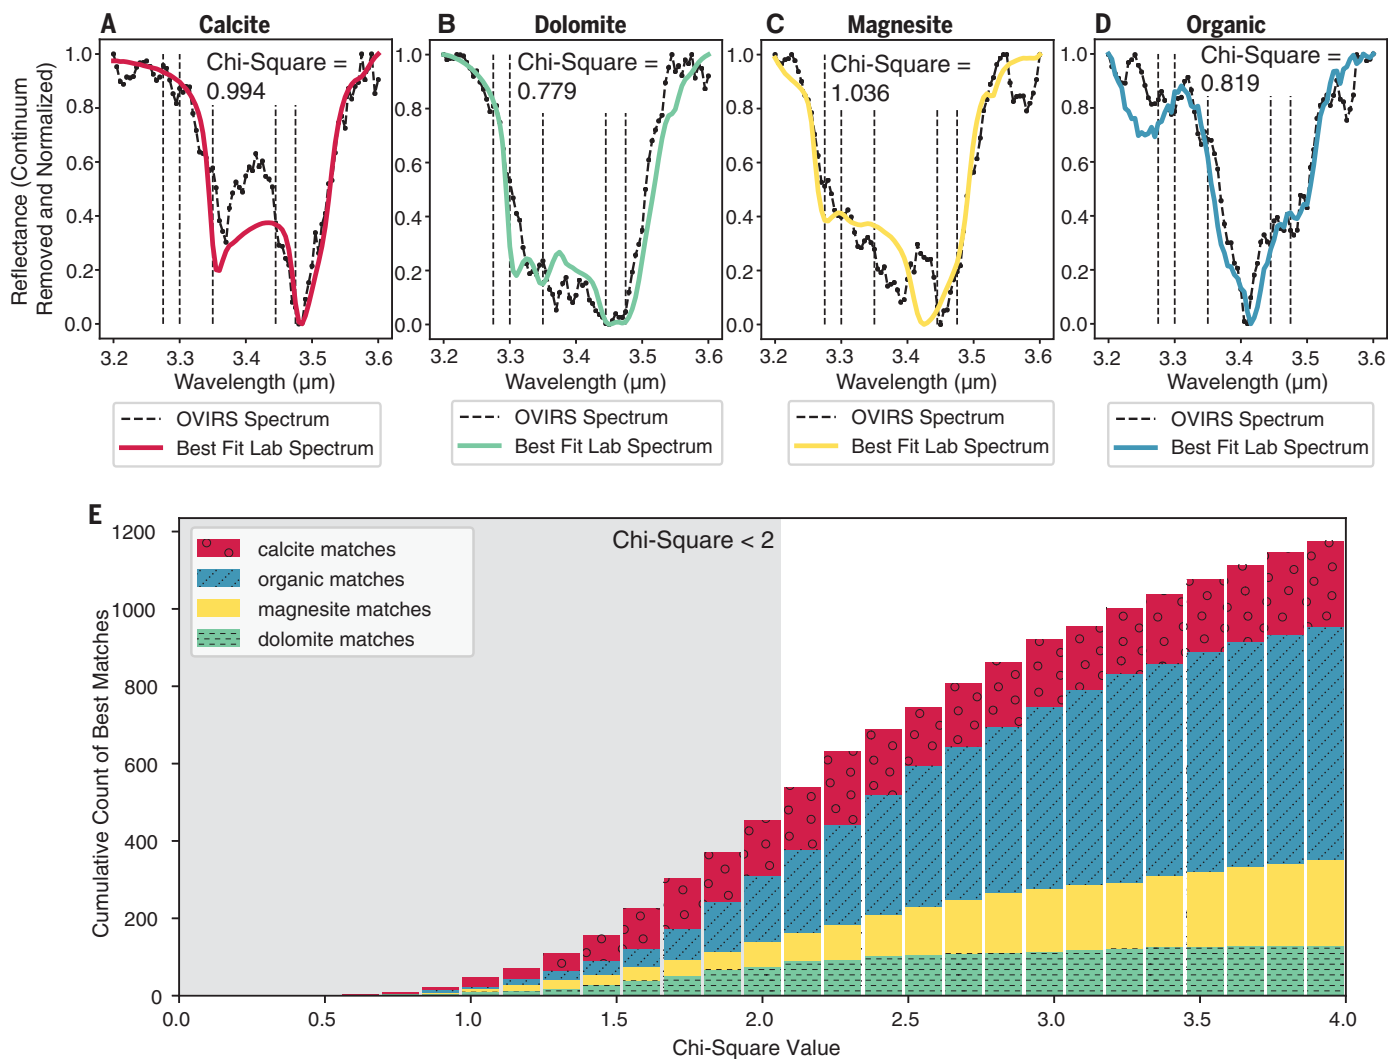

Fig. 2. Goodness of fit tests for laboratory carbonate spectra compared to OVIRS spectra. (A to D) Four different OVIRS spectra in the 3.4- μm region fit that are best fitted with laboratory spectra of calcite, dolomite, magnesite, and meteorite insoluble organic matter, respectively. (E) The cumulative count of all OVIRS spectra best fitted with either a calcite, dolomite, magnesite, or organic laboratory spectrum ordered by the chi-square value of the model. We discuss matches with chi-square < 2 (gray-shaded region) in the text.

to carbonates are strongest at the rim of Nightingale crater and on individual boulders in the area. Some of these same surface features are also associated with the strongest absorptions at 3.2 to 3.6 μm , though many are not (Fig. 4). The majority (~64%) of the carbonate signatures have band positions that are consistent with calcite, followed by magnesite/Mg-rich breunnerite (~24%) and dolomite/Fe-rich breunnerite (12%) (Figs. 2 and 3).

Bright vein-like features and mottling in boulders

To provide geologic context for the spectral observations, we examined high-resolution (~1.4 cm pixel⁻¹) images of the Nightingale region acquired by the OSIRIS-REx Camera Suite (OCAMS) PolyCam imager (30, 31) during Recon A. We found centimeter- to meter-scale features on boulders that are distinctly brighter

than the surrounding host rock. Some of these features are elongated and linear, whereas others are irregularly shaped. They are apparent in the raw camera images, with digital number (DN) values between 1.4 and 1.9 times the average value of the host rock (table S3), indicating higher reflectance than the average Benu surface.

To quantify the brightness and morphology of these features, we focused on three host boulders (Fig. 5). We radiometrically calibrated the images using the mission's standard calibration process (31). This process converts raw DN values to reflectance (also known as radiance factor or I/F), the ratio of incident solar radiation that is reflected from the asteroid to that which would be reflected from an ideal Lambertian surface normally illuminated by the Sun. The reflectance values are then used to determine the bright material's

normal albedo, defined as the reflectance at normal observing conditions (0° solar incidence, 0° solar phase, and 0° emission angles). We registered the calibrated images to digital terrain models (DTMs) of the boulders, previously produced from OSIRIS-REx Laser Altimeter (OLA) data with an average facet size of ~7 cm (19, 32). We estimated the observed photometric angles by ray tracing from the registered position and orientation of the camera to the DTMs. We used the derived angles as inputs to the Robotic Lunar Observatory photometric correction (33) to compensate for the reflectance variations resulting from changing viewing and illumination conditions. We then measured the absolute difference in normal albedo between the bright features and their host rocks.

The median normal albedo of Benu, ~4.4%, is among the lowest of any object in the Solar

Fig. 3. Band minima positions of OVIRS signatures compared to laboratory spectra of carbonates. The positions of two carbonate band minima near 3.4 μm are plotted for Benu (empty black circles), along with values for laboratory spectra (colored solid symbols; see legend and table S1). The OVIRS minima positions indicate a range of compositions on the surface. Circles are scaled to show the number of spectra represented, as indicated in the legend.

System (5, 34). Analyses of the photometrically corrected images show that the bright features have normal albedos of at least 10 to 19% (Fig. 5 and table S3). The mean normal albedo of the host boulders varies between 6.0 and 7.6% (table S3), which is also brighter than Benu's global average.

We performed further analysis of one of the bright feature-bearing boulders (labeled VBR-13 in Fig. 5, where VBR stands for vein-bearing rock) to assess the uncertainty and variability of the derived normal albedo values. This boulder was identified in 13 images taken at varying resolutions and observation geometries (table S3). In images with pixel scales ranging from 1.3 to 4.8 cm pixel^{-1} , the normal albedo of the bright material ranges from 14 to 19% ($\pm 2.2\%$, 1σ) (table S3). We rule out textural and observation geometry effects and conclude that the bright features are high-reflectance material included in the host rocks.

The three illustrative examples of the elongated, linear bright features are 3 to 15 cm thick and vary in length from 50 to 150 cm, though smaller examples exist (Fig. 6). These occur at sharp edges of boulders so may be small exposures of a larger internal layer. We interpret all these features as veins—narrow, linear features formed when an aqueous solution flows through a rock, depositing minerals by precipitation, usually within preexisting fractures. Shock processes can also create linear or planar features, and melt veins created by shock

events are found in some meteorites (35). Shock melt veins are darker than the surrounding meteorite matrix, whereas the veins on Benu are brighter than their host rocks.

The irregularly shaped bright features in darker host rocks produce a mottled appearance (Fig. 6). Similar mottled boulders occur on another C-complex asteroid, (162173) Ryugu (36). The irregular features on Benu are typically >10 cm in the longest dimension, range from angular to rounded, and can occur individually or in clusters.

The host rocks of the veins and irregular features span a range of albedos and sizes but tend to have similar morphologies. The host boulders appear to be part of a previously identified population that has a distinct, brighter albedo distribution (though not as bright as the veins and irregular features they host) relative to the dark boulders that dominate Benu's surface, and a more negative spectral slope at ultraviolet (UV) wavelengths (37). These brighter boulders also have a different texture, appearing smoother and more angular than the dark boulders on Benu. The former exhibit fractures and pits and appear to be harder and less easily broken down than the other, more hummocky observed boulder morphologies. The largest bright boulder is ~ 10 to 12 m; all of the largest boulders (≥ 20 m) on the asteroid are dark (5). In many cases, boulders that host bright veins or irregular features do so only on a single face. A few small boulders have bright material that dominates an entire face (fig. S3).

Analysis of their colors is published elsewhere (37). They have higher thermal inertias than the dark boulders, which may indicate lower porosity (38), as we expect for precipitation of vein-filling materials in fractures and void spaces.

Carbonates and veins in meteorites

Although meteorites are a biased sample of the asteroids from which they are derived, comparison may offer insight into the possible carbonate mineralogy and vein-filling materials on Benu. We therefore searched previously published studies for evidence of carbonate minerals and bright veins in the carbonaceous chondrite meteorites.

The carbonate mineralogy of carbonaceous chondrites is a function of their alteration history. CM chondrites contain on average <4 vol % carbonate (39–41). The least altered CM chondrites contain calcite as the dominant carbonate mineral (39, 42). With increasing degrees of alteration, dolomite appears, followed by breunnerite (42–44). In the most altered samples, dolomite, breunnerite, and calcite are replaced (in that order) by Fe-rich serpentine, Fe–Ni sulfides, and Mg-rich serpentine (39). In CM chondrites of all subtypes, a second generation of calcite forms after the sulfides and phyllosilicates by replacement of remaining anhydrous silicates and dolomite (39).

The carbonate mineralogy of the CI chondrites is similar to that of the most altered CMs. CI meteorites contain four types of carbonates (dolomite, breunnerite, calcite, and siderite) comprising an average of 5 vol % of the samples (24). However, the abundance of carbonates in some individual lithic fragments of CIs exceeds 10 vol %. A lithic fragment in Ivuna (a CI) has calcite as the only carbonate, which accounts for more than 20 vol % (24). Another clast has 21.5 vol % carbonate (45). A dark matrix clast in Orgueil, another CI, contains ~ 35 vol % of pure calcite (46). CIs have greater diversity in carbonate cations than CMs, including more Mg in breunnerite and magnesite. In CIs, dolomite is the most abundant carbonate phase, with breunnerite and calcite being much less abundant (24, 44, 47). Siderite is extremely rare, with only one grain reported (24).

Similar to the highly altered CMs and the CIs, the ungrouped carbonaceous chondrite Tagish Lake has a carbonate-rich lithology with calcite, dolomite, and Fe- and Mg-rich breunnerite spread diffusely through the matrix (48). The CR chondrites also have carbonates up to 5.7 vol % (49).

Most carbonates in CI and CM chondrites occur as grains 10 to 50 μm in diameter distributed throughout the matrix. However, carbonates in some carbonaceous chondrites occur as veins or vein fragments (39, 50). For

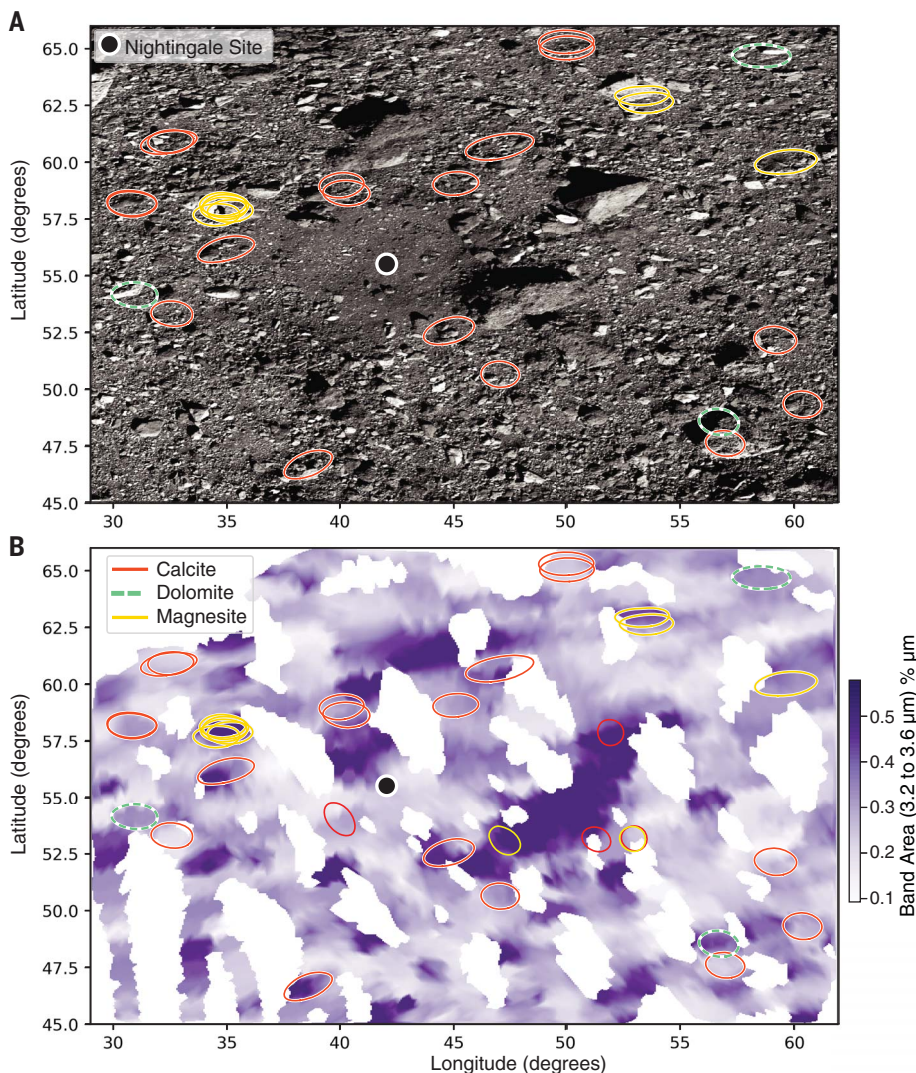

Fig. 4. Maps of carbonate-like spectral signatures at the Nightingale site and surrounding area. OVIRS footprints [colored ellipses, as indicated in the legend in (B)] of differing carbonate compositions are plotted over a panchromatic image (A) and over a map of band area from 3.2 to 3.6 μm (B). The band area does not distinguish between organics and carbonates but demonstrates overall contribution to the spectrum from carbon-bearing species. The Nightingale sample collection site is indicated with a black dot.

instance, the CM chondrite SCO 06043 is crosscut by dolomite veins hundreds of micrometers in length (39). LON 94101, another CM chondrite, contains calcite that occurs as millimeter-sized veins (50). Carbonate aggregates (~100 μm across) resembling fracture fillings have been observed in the Orgueil and Alais CI chondrites (24, 51). These have been interpreted as vein fragments that were mechanically disrupted and dispersed during breakup of the host rock (24). Veins up to ~300 μm in length are observed in Belgica 7904, a chondrite with similarities to both the CI and CM groups (52). Veins of carbonates also occur in some CR chondrites, such as in Renazzo and GRO 95577 (40, 53).

Other vein-filling minerals are found in meteorites. Fractures ≤500 μm long are filled with

smectite-chlorite in the ungrouped carbonaceous chondrite Y-82162 (54). Phyllosilicate-magnetite structures and “trains” of magnetite crystals in Orgueil have been interpreted as recrystallized veins (55). Sulfate and phyllosilicate veins occur in some CIs (44), and sulfate and Fe-rich veins are found in CMs (56). At least some of the sulfate veins are thought to be terrestrial weathering products (57).

The presence of bright, carbonate-filled veins in meteorites suggests a connection between our observations of carbonate-matching spectra and bright veins in the Nightingale area. The carbonate compositions that best match the spectral signatures on Bennu are similar to those of the CI chondrites and the most aqueously altered CM chondrites (24, 39, 43, 58), which are sometimes expressed as veins.

Composition of veins on Bennu

In addition to the spectral evidence indicative of carbonates (calcite, magnesite, dolomite, and breunnerite) that we present, known phases on Bennu’s surface include Mg-rich phyllosilicates (3), the Fe-oxide magnetite (3, 4), aliphatic organic molecules (18), and a few pyroxene-rich boulders likely originating from the Vesta asteroid family and delivered by impact (59). We consider whether any of these other phases could be potential vein-filling minerals.

Phyllosilicate veins in meteorites have similar compositions to that of their host rock (54) and therefore are unlikely to have distinct albedos from that of their surroundings, which is inconsistent with the bright veins and irregular features that we observe in host boulders. The exogenous pyroxene-bearing boulders have brighter normal albedos of ~10 to at least 26% (59). However, they have distinctive spectral features in the 1- and 2-μm region that we do not observe in OVIRS spectra covering the bright features. Sulfates are present in Bennu-analog meteorites, but the signatures observed in meteorite spectra (i.e., Ca-sulfate: distinctive features at ~1.4, 1.75, 1.9, and 2.1 to 2.2 μm) (60) are not detected in the OVIRS spectra. Magnetite and organics are optically opaque and unlikely to have the normal albedos of 10 to at least 19% observed for the bright features and veins (23, 61). Thus, although the 3.4-μm feature in some OVIRS spectra could be attributable to organics rather than carbonates (Fig. 2), the low albedo of organic-rich material means that it is not a plausible candidate for the dominant composition of bright veins on Bennu.

We conclude that carbonate is the most likely bright vein-filling material. Magnetite, sulfides, and organic phases may also be present in smaller abundances. These phases are commonly associated with carbonates in carbonaceous chondrites (45). Pure carbonates have albedos approaching 100% (62), but minor abundances of opaque minerals (e.g., magnetite and sulfides) can reduce albedo to the level of the bright features on Bennu (63). Coarser grain size can also reduce albedo (64).

Reciprocally, the bright veins and irregular high-reflectance features in boulders on Bennu are the most likely source of the carbonate-matching spectral signatures that we detected in the higher-spatial resolution OVIRS data. Hereafter, we refer to these 3.4-μm spectral signatures as carbonate signatures.

However, even at the highest spatial resolution available, OVIRS footprints are too large to isolate individual bright features. For instance, the veins in Fig. 6 only account for <0.1% of an OVIRS footprint (~28 m²), and their host boulders account for 7 to 35% of a

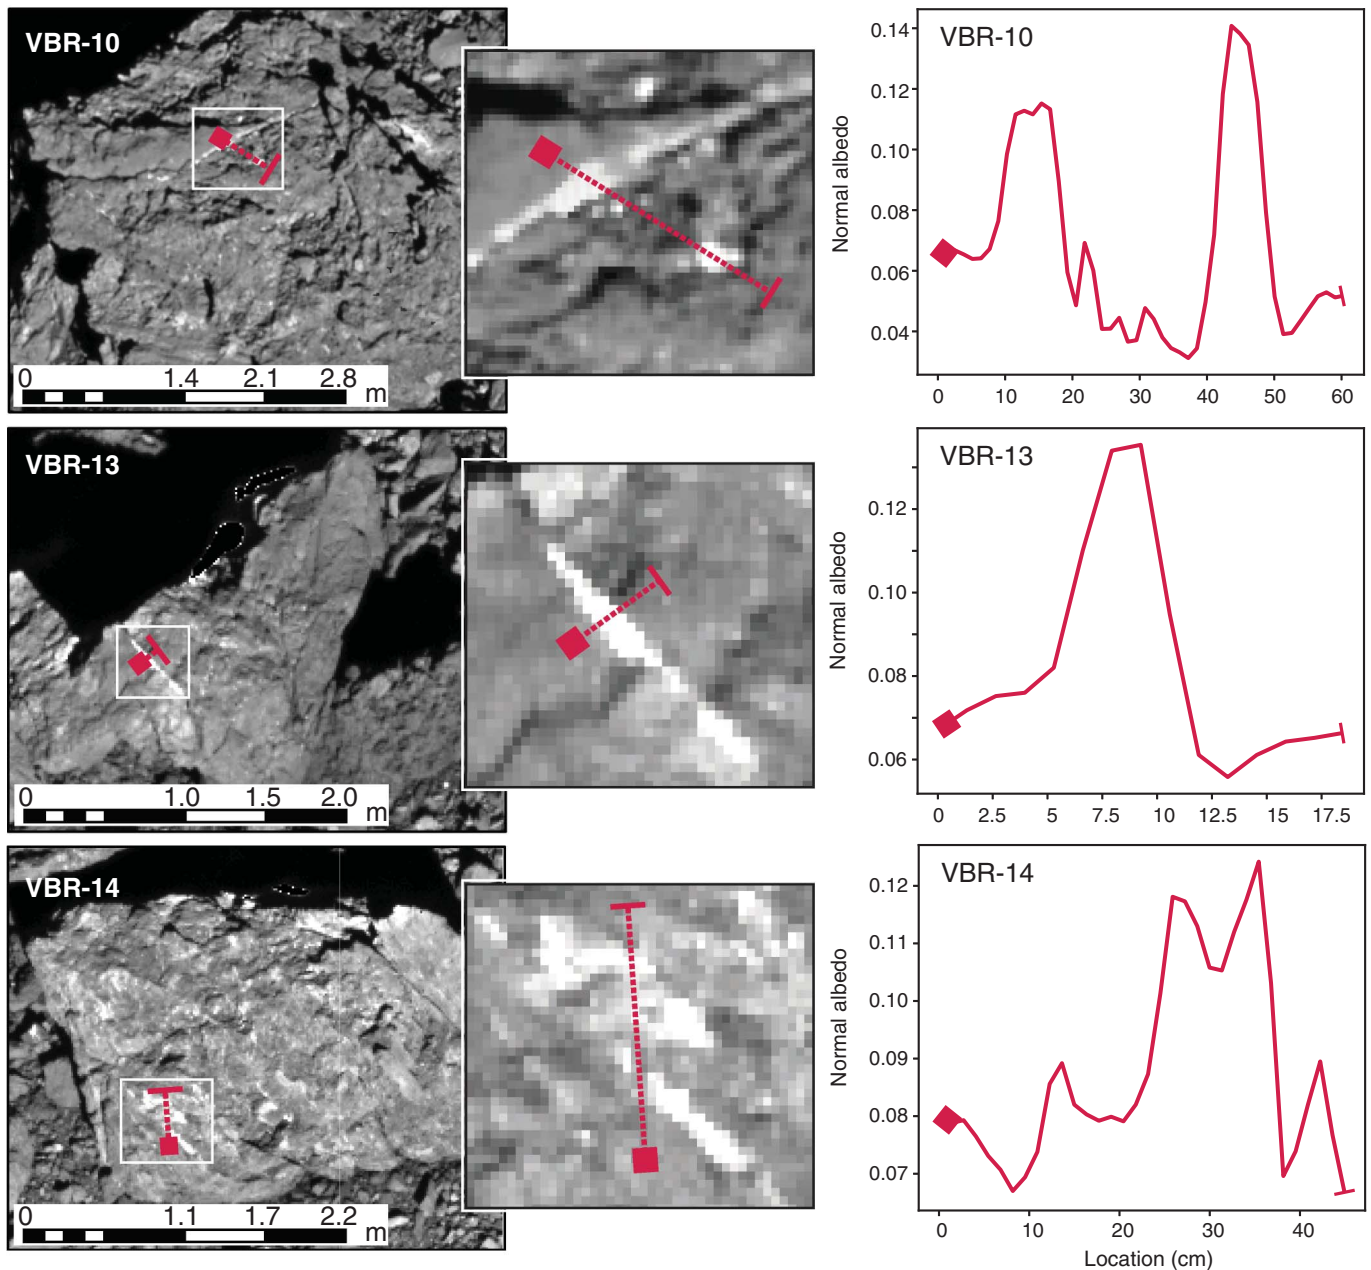

Fig. 5. Images and albedos of bright veins and irregularly shaped features on Bennu. Photometrically corrected PolyCam images (see text) of three boulders in the Nightingale region that host bright veins and irregular features. Transects across the bright features are indicated with red dotted lines, and normal albedos along the transects are plotted in the panels on the right. Albedos exceed 10%. VBR-10 is located at 51.56°N, 58.34°E; VBR-13 at 61.60°N, 50.57°E; and VBR-14 at 62.88°N, 71.55°E. Further images of the VBR-13 are shown in fig. S4.

footprint. Previous work has shown that OVIRS is highly sensitive to bright material, even in cases where it accounts for <1% of the instrument field of view (59). Changes in viewing geometries and outcroppings could block carbonate from the view of the spectrometer, explaining the variable strength of the carbonate feature in the spectral data (fig. S4).

We used a linear mixture analysis to assess whether carbonates, sequestered in veins comprising <0.1% of an OVIRS footprint, could

account for the spectral signatures that we observe (19). We found that very small fractions of carbonate, typically <0.5%, are enough to reproduce the features seen in the OVIRS spectrum (Fig. 6).

Near the Nightingale site, most of the OVIRS spots that cover veins (Fig. 6) have a calcite signature, which is the most common carbonate spectral signature on Bennu (Figs. 2 and 3). Signatures that may indicate more Mg-rich carbonates (dolomite, magnesite, breunnerite) are commonly associated with

larger, bright boulders (up to ~10 m), sometimes without visible evidence for veins or mottling (Fig. 4). Some areas have carbonate signatures with no visible veins or bright irregular features, but where small boulders consistent with the vein-hosting type are present. We attribute these detections not associated with a visible feature to more diffuse carbonate material, as would be expected in boulders or regolith where carbonate deposition may have occurred in micropores or fine veinlets, veins may have been brecciated

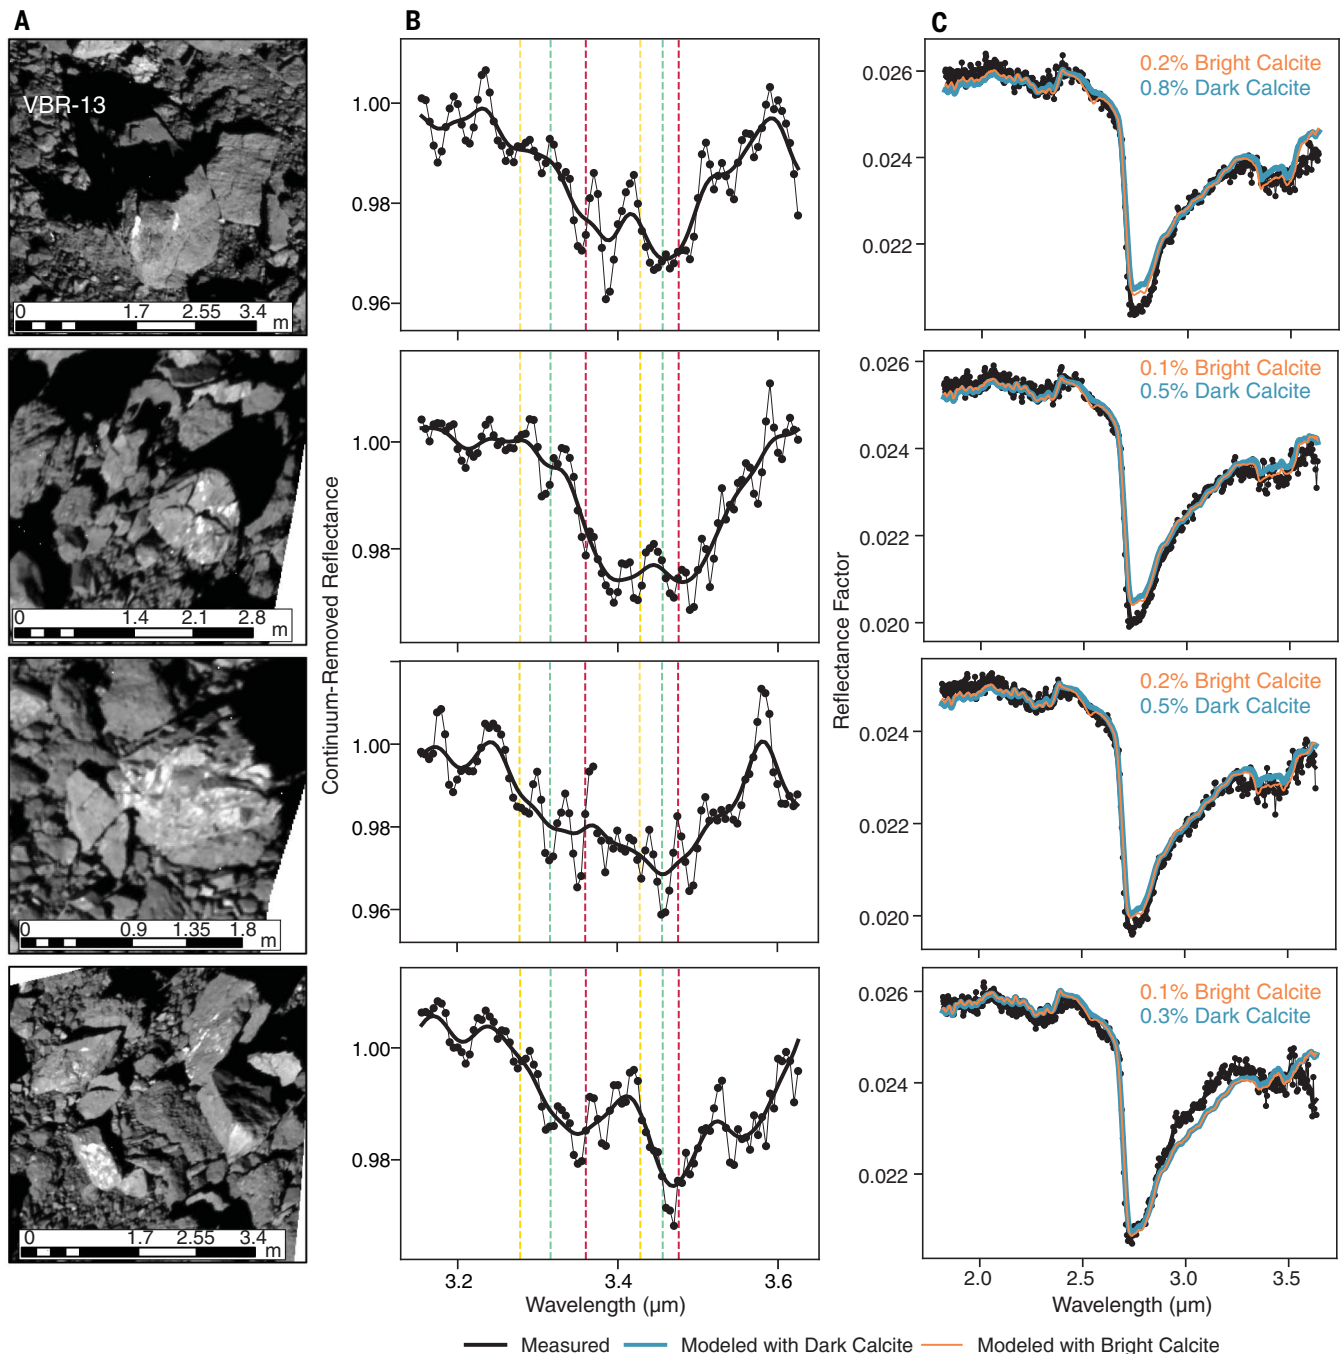

Fig. 6. Boulders with bright features and corresponding spectra. (A) PolyCam images of boulders with bright veins and irregularly shaped features in the Nightingale region. (B) OVIRS spectra of footprints that include each of these boulders have features near $3.4\ \mu\text{m}$ that may be attributable to carbonates. Dashed vertical lines indicate the positions of band minima for calcite (red), dolomite/breunnerite (green), and magnesite (yellow). (C) Linear mixture models (orange and blue lines) reproduce the observations (black data points) using a small fraction ($<1\%$) of carbonate. The extent of the OVIRS footprints is shown in fig. S6, and spectral model endmembers are in fig. S7.

and dispersed through impact gardening, or carbonates may have formed by fine-scale alteration processes that did not cause development of veins. It is also plausible that there is visible-scale carbonate-rich material within a host rock that is simply not exposed on the boulder face (e.g., VBR-14 in Fig. 5).

Conversely, we observe some veins in OVIRS spots without a strong carbonate signature. These spots tend to have spectral signatures of organics or organic-carbonate mixtures, which could indicate that a greater proportion of organics is present that is obscuring the carbonate signature, or that viewing geom-

etry effects are depressing the carbonate band depth (fig. S5) (19).

Carbonate abundances on Bennu

Though carbonaceous chondrites contain carbonate, they rarely show spectral evidence of it in the visible–near-infrared (VIS–NIR)

wavelengths covered by OVIRS (0.4 to 4.3 μm). Carbonaceous chondrites with some of the highest carbonate abundances exhibit a 4- μm carbonate absorption [e.g., Tagish Lake, (23)], but evidence of carbonate in the region from 3.2 to 3.6 μm is rarely found in meteorite spectra. Among published carbonaceous chondrite spectra, <2% have evidence for carbonate in this spectral region, with most either having no absorption or an organic absorption feature (table S4). There are no known organic-carbonate mixtures in carbonaceous chondrite spectra, suggesting that the abundances and/or spectral mixing regime on Bennu are distinct from that in the meteorites. Outcroppings of carbonate in meter-length veins could produce such a distinct spectral mixing regime, which would not be represented in meteorites.

Because carbonate has not been definitively detected in OTES spectra, we can place constraints on its abundance. For particles that are larger than the wavelength of light, thermal infrared spectra are the linear sum of the spectral signatures of all component phases in proportion to their abundance (65). Typically, such data are sensitive to individual phases at volumetric abundances of a few percent or more in laboratory and remote-sensing mixtures (66). The absence of these features suggests that, at global to regional scales, carbonate is unlikely to constitute more than a few percent of Bennu's surface mineralogy. At local scales (single to a few spectra), OTES's SNR is low at wavelengths less than ~7.4 μm , making detection of the ν_3 fundamental band challenging. At longer wavelengths, there are no substantial differences from global and regional averages in the features near 11.3 and 25 to 33 μm . This is consistent with absolute abundances of a few percent or less at the scales of most OTES global observations.

If carbonate is concentrated in the veins and irregular bright features on Bennu, it would account for only a percent or less of the area of each OVIRS spot, or 0.5% of an OTES spot (fig. S6). Such an abundance is consistent with the lack of OTES detection and with our linear mixture analysis, which indicates that only a fraction of a percent of the surface needs to be carbonate to account for the OVIRS signatures (Fig. 6). OVIRS may be particularly sensitive to carbonates if they are segregated from other surface materials and bright compared to their surroundings, as is the case for the pyroxene-bearing boulders (59). Although outcroppings of carbonate at the scales of veins observed on Bennu are not represented in the meteorite collection, the overall abundances of carbonate on Bennu may be similar to those of the meteorites (a few vol % or less). The clasts with high vol % carbonate found in some CI chondrites could result from the breakup of larger features

by impact. We expect high concentrations of carbonate in meteorites if centimeter- and meter-scale carbonate features are present on their parent bodies.

Hydrothermal alteration on Bennu's parent body

Distance

Uninterrupted veins up to 150 cm long, such as those that we observe in the OCAMS data, are too large to have formed on Bennu itself and thus must have survived from the parent body. We interpret these veins as most likely originating in the same aqueous system that is responsible for the overall level of hydration observed on Bennu.

Models of carbonaceous asteroid thermal evolution, based on meteoritic evidence, indicate that aqueous alteration was driven by hydrothermal convection [e.g., (67)]. It is unclear whether aqueous alteration occurred in a chemically closed system, in which bulk chemistry did not vary on the length scales of the meteorites, or an open system in which fluid flow promoted chemical fractionation (50). The unfractionated bulk chemical compositions of the carbonaceous chondrites appear incompatible with fluid flow over the large distances expected for open systems (13, 68, 69). Closed-system models are consistent with carbonaceous chondrite unfractionated bulk chemical compositions and their oxygen isotopes (14, 47, 67, 70, 71). The latter models are supported by the low permeability of parent body interiors (72). Open-system hydrothermal alteration scenarios suggest that fluids flowed through fractures from the interior to the exterior of the asteroid, and carbonate minerals precipitated into these fractures as veins (24). Oxygen isotope evidence has been alternatively interpreted as indicative of such open systems with large-scale fluid flow (73, 74). Numerical simulations of parent body evolution also suggest asteroid-scale fluid mobility (75–78).

The putative carbonate veins that we observe on Bennu are orders of magnitude larger than any known in meteorites. We used mass balance constraints to estimate the size of the hydrothermal systems required to produce the observed veins on Bennu. Assuming that the veins are pure calcite, they would contain 56 wt % CaO; this is an upper limit, given the lower albedo of the veins relative to pure carbonate. Previous analysis showed that the bulk abundance of CaO in Orgueil, which has major element abundances similar to the solar photosphere and hence the bulk Solar System, is 1.36 wt %, of which 0.63 wt % is soluble (46). Thus, formation of calcite veins requires a rock volume 41 times that of the vein, if all of the Ca is removed from an Orgueil-like host rock. If only the soluble component is mobilized, then the alteration

volume increases to 89 times that of the vein. The largest observed vein on Bennu is 14 cm thick. This thickness implies that a volume of host rock extending between 288 and 622 cm above and below the vein must have been leached of Ca, if carbonate fills the vein. Thus, hydrothermal alteration on Bennu would have occurred on the scale of at least meters. However, this estimate is a lower limit, as it requires substantial elemental fractionation of nearby host rocks, which is inconsistent with bulk chondritic elemental abundances.

Carbonate formation during aqueous alteration in CM chondrites would have occurred at moderate temperatures (<35°C) and pressures (<10 MPa) in the interior of a parent asteroid (69). These conditions are consistent with experiments of calcite vein formation performed at temperatures of 22° to 23°C and ambient atmospheric pressure (~100 kPa) (79). These experiments indicated that a large volume of fluid is required to produce calcite veins: typically, a fluid/calcite volume ratio of 10^5 to 10^6 for formation of thin short veins. Applying these values to the thickest veins on Bennu suggests fluid flow at the scale of 20 to 45 km on either side of the vein, implying a nearly global, open hydrologic system on Bennu's ~100-km-diameter parent body (11, 19).

Our calculations support the open-system model of asteroidal aqueous alteration. In this scenario, internal pressurization drove fluid flow from the interior of Bennu's parent asteroid through pore spaces to the asteroid surface, where water could be lost into space. As water ice melted, liquid water migrated through high-permeability fractures created by impact-induced brecciation (24, 39, 50, 58, 80). Alternatively, crack propagation could have been driven by overpressurization of gas formed during alteration (81). The reactants Ca and CO₂ were leached from host rock and transported over distances of meters to kilometers. As the hydrothermal solution cooled, calcite crystals grew into open pore spaces along the fractures, forming the veins that we observe on Bennu. This mechanism is consistent with calcite in CM chondrites having formed by cementation of fluid-filled fractures (50, 58).

Impact processing of the parent asteroid regolith could have continued after vein formation. The catastrophic disruption of the parent body and reaccumulation of rubble to form Bennu likely fractured rocks along the weak carbonate veins, potentially explaining why they are sometimes exposed on apparently broken faces. Thus, the geologic expression of the veins on Bennu has been modified by its violent history.

Time

Aqueous alteration likely proceeded progressively in multiple phases or events. Several

episodes of alteration occurred on the CI parent body (24). Coexisting calcites and dolomites in CM chondrites are not in equilibrium so also formed in distinct events (44, 80). Dolomites typically form slightly earlier than breunnerites. Extensive aqueous activity on the Orgueil parent body occurred over a period of several million years, starting ~3 to 4 million years (Myr) after formation of the Solar System (82). The probable difference in age between dolomite and breunnerite indicates temporal variations in fluid composition (82). Different carbonates (e.g., calcite, dolomite, and breunnerite) are characterized by distinct oxygen and carbon isotopic compositions [e.g., (83)]. Much of the calcite in CM chondrites represents a second generation that formed after the first-stage alteration that established the dominant phyllosilicate mineralogy [e.g., (39)]. This scenario is consistent with our observations of bright, ostensibly calcite veins hosted in fractures in phyllosilicate-rich boulders.

Carbonate precipitation time scales depend on factors such as fluid saturation state, flow velocity, vein dimension, and kinetic rate constants and reaction order. We apply a kinetic model (79) to constrain the time necessary for vein filling, finding that the veins on Benu developed on the parent body over thousands to millions of years (19).

These time scales are consistent with the timing of crystallization indicated by Mn-Cr dating of carbonates in CI and CM chondrites. Calcites and dolomites in four CM chondrites all have formation ages of $3.8_{-0.5}^{+0.4}$ Myr after the formation of the oldest Solar System solids (84). The crystallization ages of dolomite in the QUE 93005 and Sutter's Mill carbonaceous chondrites indicate that aqueous alteration occurred at a similar timing of 3.93 ± 0.23 Myr (42) and 2.4 to 5.0 Myr after the birth of the Solar System (85), respectively.

Does Benu have a meteorite analog?

Spectral data from OVIRS and OTES collected while approaching the asteroid indicated that Benu's mineralogy and chemistry were consistent with the most aqueously altered CM chondrites but did not rule out the presence of some CI-like material (3). We build on that analysis with the spectral and geologic features that we observe at Nightingale to further constrain Benu's relationship to the carbonaceous chondrite meteorites.

Benu's observed global spectral properties are broadly consistent with a highly altered CM chondrite mineralogy (e.g., CMI): Benu has a hydration band minimum at $2.74 \mu\text{m}$, a position that is associated primarily with Mg-serpentine (e.g., antigorite) but could incorporate some Fe-serpentine (cronstedtite) (3). The CIs, however, have band minima at shorter wavelengths ($2.71 \mu\text{m}$) associated with the phyllosilicates saponite and Mg-serpentine

(lizardite and chrysotile) (6). The OTES data suggest that Benu's surface is dominated by phyllosilicates, consistent with the most aqueously altered CMs (3).

Though calcite is the most common carbonate mineral that we identify on Benu, at least one-quarter of the carbonate detections are more Mg-rich compositions based on the wavelength of their $3.4\text{-}\mu\text{m}$ features (Fig. 3), including likely dolomite, breunnerite, and magnesite. Only calcite, breunnerite, and dolomite have been found in CM chondrites, possibly because Mg is limited to dissolution from olivine, which occurs in only the most altered CMs (39, 43). Magnesite has only been reported in the CIs (47, 86) and in some ungrouped carbonaceous chondrites (87), so the presence of magnesite on Benu could imply a closer relationship to these meteorites. However, calcites still account for the largest individual fragments in the CIs (46), and vein-filling calcites are found in both CIs and CMs (24, 39, 51).

CM and CI meteorites are usually assumed to originate from different asteroid parent bodies. The bright veins and irregular features on Benu are associated with a specific boulder morphology and reflectance range, so they could have a different composition, and thus a distinct source, from that of the other boulders on Benu. However, though the vein-bearing boulders belong to a population with distinctive albedo and color (37), there is no indication that the hydration band minimum position or depth for these boulders is different from that of the rest of Benu (18), though much of the spectral data have a spatial resolution too low to isolate individual boulders of this type. Benu's rubble-pile structure and diverse boulder morphologies are consistent with a mixture of compositions from multiple locations within its parent asteroid.

Benu may bear the closest resemblance to the ungrouped carbonaceous chondrite meteorites with similarities to both CMs and CIs. For instance, the ungrouped carbonaceous chondrite Tagish Lake has mineralogy, oxygen isotope, and bulk chemical composition that fall between those of the CMs and CIs (88). It has a carbonate-rich lithology that contains both calcite and Fe,Mg-carbonates intermixed with saponite and magnetite clasts (88). Tagish Lake is dynamically and spectrally linked to outer main belt C-complex asteroids with red spectral slopes (89), so we do not suggest that it is directly related to the blue-sloped Benu. However, Benu may similarly represent an ungrouped, intermediate composition of chondritic material. The bright centimeter-scale irregular features and meter-scale veins on Benu, which are also not represented in meteorites, may be characteristic of this particular material; alternatively, it may be common on carbonaceous

chondrite parent bodies but only observed on Benu, where we are able to make observations at the outcrop scale. Mottled boulders on Ryugu could be a similar expression of bright, carbonate-bearing material; however, this cannot be confirmed with the spectrometer on Hayabusa2, which does not cover the $3.4\text{-}\mu\text{m}$ region.

Vein fragments in carbonaceous chondrites could be rare because most carbonate veins have been broken up and scattered by impacts (44, 51). Carbonate veins may be preferentially destroyed by the ejection process and/or passage through Earth's atmosphere, reducing the likelihood of being represented in the meteorite record. Meteorite collection parties might not recognize carbonate-rich fragments as possible meteorites.

Role of space weathering

Space weathering can modify the spectrum of an exposed surface, complicating comparison between in situ spectra of Benu and the interiors of meteorites. The influence of space weathering on Benu's spectral properties is only partly understood. The bright boulder population that hosts the veins and irregular features appears more resistant to space weathering than dark boulders on Benu (37). Irradiation experiments performed on meteorites indicate that a wide range of changes in VIS-NIR spectral slope are possible (90). Space weathering can destroy aliphatic organics (91), which could explain the variable organic and carbonate mixture signatures that we observe with OVIRS. In this scenario, more recently exposed surfaces would have stronger organic absorptions that weaken with time. Benu is known to eject particles from its surface; the mechanism is unknown but could expose material from the interior (92). The spectral signature of carbonate and mixtures, where present, still implies either an unexpectedly high abundance or, more likely, an unusual outcropping of carbonate, compared to the carbonaceous chondrite spectra.

OSIRIS-REx's sampling mechanism is designed to collect the top several centimeters of Benu's regolith (93), whereas the spectrometers only measure the top tens to hundreds of micrometers. Thus, space-weathered material may be in the minority of the collected sample, unless regolith mixes on the centimeter scale on time scales longer than the rate of space weathering. Material attached to the spacecraft's surface contact pads could distinguish surface-exposed material from un-space-weathered material in the near subsurface.

Thermal evolution and organics

Most aqueous alteration in the CIs and CMs occurred at temperatures $<150^\circ\text{C}$, but some meteorites have experienced additional heating to higher temperatures (86). Carbonates

decompose at ~400° to 800°C depending on cation (94), suggesting that the carbonates on Bennu were not exposed to these higher temperatures, at least not for a sufficiently long period to decompose them all. The pervasive 2.7- μm hydration feature, with no spectral evidence for volumetrically abundant anhydrous silicates such as olivine and pyroxene (3), indicates that the phyllosilicate that is widespread on Bennu has not been dehydrated or decomposed (which is nearly complete by 700°C), nor has it formed detectable secondary olivine (which occurs by 800°C) (95).

The temperature and duration of aqueous alteration of the materials on Bennu, and their thermal metamorphism, will affect the abundance and distribution of both soluble and insoluble organic matter in the returned samples. The presence of aliphatic organics across Bennu's surface places a stricter limit on peak temperatures than the carbonates, because thermal alteration quickly destroys aliphatic bonds (96). The 3.4- μm spectral feature from aliphatic organics in insoluble organic matter (IOM) is lost within ~200 years at 100°C (97). CMs with organic spectral features therefore experienced <15°C heating over the duration of aqueous alteration, potentially further limiting the range of temperatures experienced by organic-rich regions on Bennu. It is possible that organic-rich boulders and carbonate-rich boulders are distinct populations (40, 41), with different thermal histories. The thermal gradient within an asteroid parent body similar to Bennu's spans a range of hundreds of degrees Celsius (73), and this gradient, along with spatial heterogeneity in pore water flow, could account for the range of compositions inherited by Bennu.

Conclusions

Remote-sensing observations provide outcrop-scale information, on scales larger than meteorite samples. Bennu shares compositional traits with aqueously altered CM and CI meteorites, including the presence of Mg-phyllosilicates, magnetite, and, we posit, carbonate mineralogy dominated by calcite, with smaller amounts of magnesite, dolomite, and breunnerite. However, the carbonate spectral dominance in OVIRS data at 3.4 μm is unusual compared to meteorite spectra. We observe bright veins with thicknesses of 3 to 15 cm and lengths that can exceed 1 m. We propose that they are composed of the spectrally detected carbonates. On the basis of the vein dimensions, which are much larger than any veins found in meteorites, a hydrothermal system of at least 89 times the volume of the veins, or an amount of fluid at least 10^5 times the volume of the veins, would have been required to leach the elements from the surrounding host rock. Fluid flow on Bennu's parent body would have taken place over distances of kilometers

for thousands to millions of years. We predict that the returned sample could contain carbonates with structure and scale distinct from those in the meteorites.

It remains unclear whether these differences arise from material that would not survive delivery to Earth as a meteorite, or because Bennu's parent body is distinct from the CM or CI parent body. Bennu is unlikely to be the only object of its kind in the asteroid population, as most asteroids have not been visited by spacecraft. Large-scale open-system hydrothermal alteration may therefore have occurred on carbonaceous parent bodies more generally. Ceres, the only other known carbonate-bearing asteroid that has been visited by a spacecraft, experienced extensive hydrothermal alteration, beyond the degree of the most hydrated (CI group) meteorites (98). This extensive alteration along with more recent geologic activity (99) may have obscured evidence of the earliest stages of alteration, including vein formation. Whether distinct or representative, the returned sample from Bennu is likely to contain carbon-bearing species in the form of organics and/or carbonates.

ACKNOWLEDGMENTS

We are grateful to C. W. V. Wolner for editorial review. We acknowledge the entire OSIRIS-REX Team for making the encounter with Bennu possible. **Funding:** Supported by NASA under Contract NNM10AA11C issued through the New Frontiers Program. **Author contributions:** H.H.K., D.S.L., A.A.S., and V.E.H. contributed to the conceptualization, formal analysis, and methodology of the paper; H.H.K., A.A.S., V.E.H., C.A.B., D.N.D., D.R.G., D.C.R., J.P.E., K.N.B., X.-D.Z., M.G.B., O.S.B., and J.A.S. performed data curation; H.H.K. was primarily responsible for

visualization; K.I., N.P., and E.R.J. contributed methodology and formal analysis and helped with visualization; T.D.G. carried out investigation; D.S.L. and H.L.E. are responsible for project administration; H.H.K., D.S.L., A.A.S. V.E.H., D.N.D., D.R.G., D.C.R., K.N.B., H.C., H.C.C., J.P.D., J.P.E., D.P.G., T.D.G., R.H., K.I., E.R.J., T.J.M., N.P., S.A.S., S.F., B.E.C., X.-D.Z., M.G.D., O.S.B., and J.A.S. contributed to writing the original draft of this paper and contribution of ideas. **Competing interests:** We declare no competing interests. **Data and materials availability:** OVIRS spectral data from the Reconnaissance A phase are available via the Planetary Data System (PDS) at <https://sbn.psi.edu/pds/>

[resource/orex/ovirs.html](https://sbn.psi.edu/pds/resource/orex/ovirs.html); data from the Nightingale site flyby have filenames starting with the dates of data collection, 2019-10-26 to 2019-10-27. OCAMS (PolyCam) images from the Reconnaissance A phase are available on the PDS at <https://sbn.psi.edu/pds/resource/orex/ocams.html>. File names for the data we used are given in table S3. Calcite, siderite, magnesite, and dolomite laboratory spectra (Figs. 1 to 3) were taken from RELAB (www.planetary.brown.edu/relab/) and the USGS Spectral Library (www.sciencebase.gov/catalog/item/5807a2a2e4b0841e59e3a18d); the spectra identifiers we used are listed in table S1. A catalog of our spectral classifications is provided in Data S1.

The complex history of Bennu's surface

The near-Earth asteroid (101955) Bennu is a carbon-rich body with a rubble pile structure, formed from debris ejected by an impact on a larger parent asteroid. The Origins, Spectral Interpretation, Resource Identification, Security, Regolith Explorer (OSIRIS-REx) spacecraft is designed to collect a sample of Bennu's surface and return it to Earth. After arriving at Bennu, OSIRIS-REx performed a detailed survey of the asteroid and reconnaissance of potential sites for sample collection. Three papers present results from those mission phases. DellaGiustina *et al.* mapped the optical color and albedo of Bennu's surface and established how they relate to boulders and impact craters, finding complex evolution caused by space weathering processes. Simon *et al.* analyzed near-infrared spectra, finding evidence for organic and carbonate materials that are widely distributed across the surface but are most concentrated on individual boulders. Kaplan *et al.* examined more detailed data collected on the primary sample site, called Nightingale. They identified bright veins with a distinct infrared spectrum in some boulders, which they interpreted as being carbonates formed by aqueous alteration on the parent asteroid. Together, these results constrain Bennu's evolution and provide context for the sample collected in October 2020.
